The Genetic Algorithm of GMSE

GMSE: an R package for generalised management strategy evaluation (Supporting Information 1)

Extended introduction to the genetic algorithm applied in GMSE

Game theory is the formal study of strategic interactions, and can therefore be applied to modelling stakeholder actions and addressing issues of cooperation and conflict in conservation (Lee, 2012; Kark et al., 2015; Adami et al., 2016; Tilman et al., 2016; Redpath et al., 2018). In game-theoretic models, agents adopt strategies to 10 make decisions that maximise some type of payoff (e.g., utility, biological fitness). Agents are constrained in 11 their decision-making, and realised pay-offs depend on decisions made by other agents. In simple models, it is 12 often useful to assume that agents are perfectly rational decision-makers, then find optimal solutions for pay-off 13 maximisation mathematically. But models that permit even moderately complex decision-making strategies 14 or pay-off structures often include more possible strategies than are mathematically tractable (Hamblin, 2013). 15 In these models, genetic algorithms, which mimic the process of natural selection (mutation, recombination, 16 selection, reproduction), can find adaptive (i.e., practical, but not necessarily optimal) solutions for game 17 strategies (e.g., Balmann and Happe, 2000; Tu et al., 2000; Hamblin, 2013). 18

A genetic algorithm is called in the predefined GMSE manager and user models to simulate human decision 19 making. As of GMSE version 0.6, this includes one independent call to the genetic algorithm for each 20 decision-making agent in every GMSE time step. Therefore, one run of the genetic algorithm occurs to simulate the manager's policy-setting decisions in each time step (unless otherwise defined through non-default 22 manage_freq values greater than 1; e.g., see SI6), and one run occurs to simulate each individual user's 23 action decisions in each time step (unless otherwise defined through non-default group_think = TRUE, in which case one user makes decisions that all other users copy). Each run of the genetic algorithm mimics the 25 evolution by natural selection of a population of potential manager or user strategies over multiple iterations, with the highest fitness strategy in the terminal iteration being selected as the one that the manager or user 27 decides to implement. For clarity, as in the main text, we use 'time step' to refer to a full GMSE cycle (in which multiple genetic algorithms may be run) and 'iteration' to refer to a single, non-overlapping, generation 29 of potential strategies that evolve within a genetic algorithm (see Figure 1 of the main text). Below, we explain the genetic algorithm in detail, as it occurs in GMSE v0.6 (future versions of GMSE might expand 31 upon this framework, and we highlight some of these potential avenues for expansion). We first explain the key data structures used, then provide an overview of how a population of strategies is initialised, and the 33 subsequent processes of crossover, mutation, cost constraint, fitness evaluation, tournament selection, and replacement. We then explain the fitness functions of managers and users in more detail.

36 Key data structures used

The focal data structure used for tracking manager and user decisions is a three dimensional array, which
we will call ACTION (also returned as user_array by gmse_apply; see SI7). Rows of ACTION correspond to
the entities affected by actions (resources, landscape properties, or potentially other agents), and columns
correspond either to properties of the affected entities, or to the actions potentially allocated to them. Each
layer of ACTION corresponds to a unique agent, the first of which is the manager; additional layers correspond
to users. Below shows an ACTION array for a GMSE model with one manager and two users.

The above array holds all of the information on manager and user actions. The first seven columns contain

information about which entities are affected, and how they are affected. The first column Act identifies the type of action being performed; a value of -2 defines a direct action to a resource (e.g., culling of the resource), and a value of -1 defines direct action to a landscape (e.g., increasing yield). Positive values are 90 currently only meaningful for Manager_Actions, where a value of 1 defines an action setting a uniform cost of users' direct actions on resources (i.e., costs where Act = -2 for User_1_Actions and User_2_Actions). 92 All other values for Act are meaningless in GMSE 0.6, but might be expanded upon in future versions to allow for modification of specific user costs enacted by managers (i.e., managers having different policies for different users) or other users (e.g., users increasing the costs of other users' actions due to conflict or cooperation). We will therefore focus only on rows 1-3 of ACTION.

Columns 2-4 refer to resource or landscape types, but only Type_1 = 1, Type_2 = 0, and Type_3 = 0 are allowed in predefined GMSE v0.6 manager and user sub-models (i.e., only one type of resource is permitted). Future versions might allow for different resource types (e.g., Type_1 might be used to designate species, and Type_2 and Type_3 could designate stage or sex). Column 5 Util. of ACTION defines the utility associated with the resource (where Act = -2) or landscape (where Act = -1). For managers, the target resource abundance set with the GMSE argument manage_target is found in row 1 (1000 in ACTION above); for users, the value in row 1 identifies whether resources are preferred to increase (if positive) or decrease (if negative). Values of column 5 in row 2 similarly identify whether landscape cell output is preferred by users to increase or decrease (managers do not currently have preferences for landscape output). Of special note is row 3 for Manager Actions, which defines the *current* manager's utility for resources; that is, the adjustment to resource abundance that the manager will attempt to make based on the manage target and the most recent estimate of resource abundance produced by the observation model (in the case of the above, resource abundance is estimated at ca 1065.76, so the manager will set policy in attempt to change the population size by ca -65.76 resources). Column 6 U land defines whether or not the utility attached to the resource or landscape output depends on it being on a landscape cell that is owned by the acting user. Related, column 7 U loc. defines whether or not actions can be performed only on a landscape cell that is owned by the acting user. Hence values of columns 6 and 7 are binary, and affected by the land_ownership argument in gmse and gmse_apply. Finally, columns 8-13 correspond to specific actions, either direct (where Act < 0) or indirect by setting policy (for row 3 of Manager_Actions where Act = 1). The last column 13 None corresponds with no actions. See GMSE documentation for details about the effects of each action.

Constraints on the values that elements in the ACTION array can take are defined by a COST array (also returned as manager_array by gmse_apply; see SI7) of dimensions identical to ACTION. Elements of COST define how many units from the manager_budget or user_budget are needed to perform a single action; a minimum_cost for actions is defined as an argument in GMSE (10 by default). All values in COST columns 1-7 are set to 100001, one higher than the highest possible manager budget or user budget, so neither managers nor users can affect resource types or utilities. Columns 8-13 are also set to 100001, except where actions are allowed. Maximum values of 100000 are independent of any other parameter value specified in GMSE (e.g., landscape dimensions). Below shows the COST array that corresponds to the above ACTION array.

Note that in default GMSE parameters, culling = TRUE, but all other actions are set to FALSE. Hence, the Cull column 9 is the only column besides column 13 None in which cost is less than 100001. Manager's actions in ACTION directly affect the cost of users performing one of the five possible actions on resources (columns 8-12). This can be verified in ACTION where the manager has set the cost of culling to 65 (row 3), and the corresponding COST of resource culling is 65 for both users (row 1). The cost of the manager affecting the cost of user actions is always set to the minimum_cost; here the default 10 is used. This minimum_cost also defines cost values for None, in which the user or manager does nothing, as might occur if the manager wants to permit culling and therefore does not want to invest any of their manager_budget to increasing the cost of culling. Both ACTION and COST are updated in each time step unless manage_freq > 1, in which case COST and Manager Actions in ACTION are updated at the frequency defined.

The genetic algorithm updates a single layer of the ACTION array, which defines the decisions of a single agent (either the manager or a user). The corresponding layer of the COST array remains unchanged, and serves only to ensure that ACTION values do not exceed manager_budget or user_budget for managers and users, respectively. The genetic algorithm proceeds by first initialising a large (but temporary) population of new ACTION layers. In each iteration, these layers crossover and mutate, generating variation in potential agent decisions; costs constrain this variation from exceeding a maximum budget, then the fitness of each layer is evaluated based on how the layer is predicted to affect resources or landscape output to which the agent has assigned some utility. A tournament is used to select high fitness layers, and these selected layers become the new iteration of layers; iterations continue until a minimum number of iterations (ga_mingen) have passed and a convergence criteria is satisfied such that the increase in mean fitness from the previous iteration is

below the threshold converge_crit (Figure 1 below).

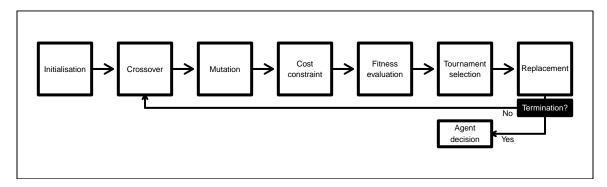

Figure 1: Conceptual overview of the GMSE genetic algorithm

91 Initialisation

At the start of each genetic algorithm, a population of size ga popsize is initialised (hereafter the POPULATION 192 array). This population is held in a 3D array of ga popsize layers. Each layer includes an identical number 193 of rows and columns as in ACTION, and one layer defines a single 'individual' in the population. The first seven 194 columns of ACTION are replicated exactly for all individuals, and remain unchanged throughout the genetic 195 algorithm thereby preserving the information about which entities are affected by actions in a given row. The 196 remaining columns are either also replicated exactly as in ACTION (i.e., initialised to be the same decisions 197 as in a previous time step), or randomly seeded with values given the constraints of manager_budget or 198 user_budget (i.e., initialised to random decision making). The number of exact replicates initialised is set 199 using ga_seedrep (if ga_seedrep \geq ga_popsize, then all individuals are seeded as replicates). After the 200 POPULATION of ga_popsize individuals is initialised, a loop simulating the adaptive evolution of POPULATION 201 in non-overlapping iterations begins (see Figure 1 above). 202

203 Crossover

A single iteration of the genetic algorithm begins with a uniform crossover (Hamblin, 2013), by which actions of individuals in POPULATION are randomly swapped with some probability. To implement crossover, each individual selects a partner, then exchanges corresponding array elements affecting agent actions (columns with their partner at a fixed probability of ga_crossover.

Mutation

Following crossover, POPULATION array elements affecting agent actions (columns 8-13) mutate at a fixed probability of ga_mutation. For each array element, a random uniform number $u \in [0, 1]$ is sampled. If u is greater than 1 - (0.5 * ga_mutation), then the value of the array element is increased by 1. If u is less than 0.5 * ga_mutation, then the value of the array element is decreased by 1; when this decrease results in a negative value, the mutated value is multiplied by -1 to be positive.

214 Cost constraint

Variation in manager or user actions generated by crossover and mutation might result in strategies that
exceed manager_budget or user_budget, respectively. Left unchecked, this over-budgeting could lead to
unnacceptably high fitness strategies, so strategies that are over budget following crossover and mutation
need to be brought back within budgetary constraints. To do this, the genetic algorithm first checks to see if

an individual in POPULATION is over budget. If so, then an action is randomly selected and removed, and budget use is reassessed; this random removal of an action and subsequent budget reassessment continues until the individual does not exceed their budget.

241

242

244

245

246

247

248

249

250 251 Once all individuals in POPULATION are within budget, the fitness of each individual is assessed. Fitness assessment works differently for managers versus users because managers need to consider the consequences of their decisions on user actions, and how those actions will affect resource abundance. In contrast, user actions need to consider the consequences of their decisions on resource abundance or landscape output. Individual fitness is defined by a real number that increases with the degree to which an individual's actions are predicted to increase entities of positive utility and decrease entities of negative utility (recall that managers and users assign resources or landscape output a utility value). Details for how fitness is calculated are provided below.

230 Tournament selection

After each individual in POPULATION is assigned a fitness, a tournament is used to select individuals. Tourna-231 ment selection is an especially flexible, non-parametric method that samples a subset of individuals from 232 the total population and chooses the fittest of the subset for replacement (Hamblin, 2013). In GMSE, 233 tournament selection proceeds by randomly sampling ga sampleK individuals from the total POPULATION 234 with replacement. The fitnesses of the subset of ga_sampleK individuals are compared, and the ga_chooseK 235 individuals of highest fitness are retained (if ga sampleK > ga chooseK, then all ga sampleK are chosen, but 236 this will prevent adaptive evolution and is therefore not recommended). Tournaments selecting ga_chooseK 237 individuals from random subsets of size ga_sampleK continue until a total of ga_popsize individuals are 238 retained.

$_{\scriptscriptstyle{240}}$ Replacement and termination

Once a new set of ga_popsize individuals is retained through tournament selection, these individuals replace the previous POPULATION array. The genetic algorithm terminates if and only if a minimum number of iterations has passed (ga_mingen) and a convergence criteria (converge_crit) is satisfied. The convergence criteria checks the difference between the mean fitness of individuals in the new iteration versus the previous iteration; if this difference is greater than converge_crit, then termination does not occur (this prevents termination from occuring while fitness is still increasing, though it is usually fine to use the default GMSE converge_crit = 0.1 and ga_mingen = 40, which nearly always terminates the genetic algorithm after 40 iterations having identified adaptive manager or user strategies). Due to the way in which fitness is calculated (see below), in practice, converge_crit currently applies only to users. If termination conditions are not satisfied, then the POPULATION of individuals begins a new iteration of crossover, mutation, cost constraint, fitness evaluation, and tournament selection (Figure 1).

Detailed explanation of manager and user fitness functions

Here we explain how the fitnesses of candidate manager and user strategies in a POPULATION array (see above)
are calculated. We emphasise that the fitness functions used in GMSE v0.6 are intended to be heuristic
tools for identifying reasonable manager and user behaviours. In practice, our fitness functions identify
behaviours that are well-aligned with manager and user interests for harvesting or crop yield, but they are
not intended to identify optimal decisions. This practical, metaheuristic approach is consistent with the
objectives of management strategy evaluation (Bunnefeld et al., 2011), and is well-suited for the use of genetic
algorithms (Hamblin, 2013). Luke (2009) describes the metaheuristic approach more generally (original
emphasis retained):

Metaheuristics are applied to *I know it when I see it* problems. They're algorithms used to find answers to problems when you have very little to help you: you don't know beforehand what the optimal solution looks like, you don't know how to go about finding it in a principled way, you have very little heuristic information to go on, and brute-force search is out of the question because the space is too large. *But* if you're given a candidate solution to your problem, you *can* test it and assess how good it is. That is, you know a good one when you see it.

Given the complexity of adaptive management and socio-ecological interactions, the above conditions for applying the metaheuristic approach are clearly satisfied for manager and user decisions. With this in mind, we now explain the details of manager and user fitness functions; that is, how GMSE assesses whether or not a strategy is a good one.

Fitness function for managers

Individual fitness as calculated for managers (F_i^m) is affected by a manager's utility for resources and the projected change in resource abundance caused by the individual's policy (i.e., the contents of their POPULATION layer, specifically row 3; here again we use 'individual' to refer to one of ga_popsize discrete strategies in POPULATION, which may be selected and reproduce within the genetic algorithm). Manager utility for a resource (U_{res}^m) is defined as the difference between manage_target and the estimation of population abundance as produced by the GMSE observation model (see "Key data structures used" above, and SI7 for more information). Manager utility can therefore change in each GMSE time step as estimated resource abundance changes; when the estimated resource abundance is greater than manage_target, U_{res}^m is negative, and when the estimated resource abundance is less than manage_target, U_{res}^m is positive. To get the fitness of individuals, first the change in resource abundance predicted by the individual's policy (ΔA_i) is calculated, then the squared difference between ΔA_i and U_{res}^m is calculated to obtain a utility deviation (D_i) for the individual i,

$$D_i = (\Delta A_i - U_{res}^m)^2.$$

The value of D_i increases as ΔA_i gets further from U^m_{res} ; i.e, D_i is high when i sets a policy that is not predicted to get closer to the manage_target abundance. Fitness is defined by first finding the maximum D_i value among all ga_popsize individuals (D_{max}) , then subtracting D_i from this value for each individual,

$$F_i^m = D_{max} - D_i.$$

We have explained how U_{res}^m is calculated in the above section on key data structures. We now explain in more detail how individuals in the genetic algorithm calculate how their actions will affect ΔA_i .

To predict change in resource abundance as a consequence of policy, an individual first needs to know the total number of actions of all types j (e.g., scaring, culling, etc.) performed by users in the previous time step $(X_{\bullet,j};$ note that this value includes the increment manage_caution, with a default of manage_caution = 1, to ensure that managers do not naïvely assume that users will not perform an action just because they did not perform it in the previous time step), and the cost of performing each action $(C_{\bullet,j})$. This information is collected from ACTION and COST arrays. The individual i then needs to predict how their policy (i.e., the costs that they set for users to perform an action) will affect the new total number of each action j performed $(X_{i,j})$. To do this, the individual assumes that total user actions performed under their policy will change in proportion to that of the old policy, while also recognising that users have a maximum above which higher costs set by the manager will have no effect. Interested readers might wish to examine the short new_act function, which is summarised mathematically below; this function is called by the policy_to_counts function in the genetic algorithm source file.

The manager first calculates how much total budget, as summed over all users, was devoted to an action by multiplying the old per action cost $C_{\bullet,j}$ by the total number of actions performed, $X_{\bullet,j}$. The manager then divides this by the new cost $C_{i,j}$ per action to calculate the new predicted number of actions,

$$X_{i,j} = \frac{X_{\bullet,j} \times C_{\bullet,j}}{C_{i,j}}.$$

Note again that if $C_{i,j} = C_{\bullet,j}$, then the total number of new predicted actions j will remain unchanged. If $C_{i,j} > C_{\bullet,j}$, then the total number of new actions will decrease, and if $C_{i,j} < C_{\bullet,j}$, then the total number of new actions will increase.

The predicted consequences of $X_{i,j}$ for resource abundance differ for each possible action. For each action, no consequence is predicted if the policy is not allowed by a simulation of GMSE (e.g., culling = FALSE). 308 For allowed actions, the parameter manager_sense (σ) modulates predicted consequences for abundance by some factor; this is useful because not all actions attempted by users will be realised, and a value of $\sigma = 1$ 310 tends to slightly overestimate how much the actions attempted by users will actually translate to a change 311 in resource abundance. In practice, the default $\sigma = 0.9$ usually performs well. Managers also have access 312 to an estimate of the number of offspring that resources produce (E[offspring]). For default settings in 313 GMSE v0.6, $E[offspring] = \lambda$, where λ is the GMSE argument lambda that defines the baseline population 314 growth rate of resources. Given a non-default GMSE argument for consume_repr (where consume_repr is 315 how much consumption of landscape yield is needed to increment offspring production by 1), E[offspring] is 316 further incremented by ((times_feeding * res_consume) / consume_repr) to account for reproduction 317 enabled by feeding on the landscape (res_consume is the proportion of landscape yield that a resource 318 consumes during feeding). 319

Allowed actions are predicted by managers to have the following effects (again, we emphasise that whether or not these effects are realised will depend later on the user model, to which the manager – by design – does not have access):

- scaring is assumed to be nonlethal and therefore have no effect on resource number (resources are moved to a random cell on the landscape, as sampled from a uniform distribution such that movement to any given cell is equally probable).
- culling decreases resource number by $\sigma(1 + E[offspring])$.
- castration decreases resource number by $\sigma(E[offspring])$.
- feeding increases resource number by $\sigma(E[offspring])$.
- help_offspring increases resource number by σ .

Note that σ is included in all of the predicted actions above as a modulator for how strongly the manager predicts users will respond to a change in manager policy (e.g., a value of 0 would predict no reaction on the part of users to a change in policy, while a value of 1 would predict that an action would increase in exact proportion to its decrease in cost).

The above effects cannot be altered directly in gmse or gmse_apply (though parameter values can of course be changed using manager_sense and arguments affecting E[offspring]), but future versions of GMSE might include different predicted effects to increase precision or allow for multiple resource types or different actions. The summation of $X_{i,j}$ for all actions defines the predicted change in resource abundance caused by the policy of an individual i, ΔA_i .

Fitness function for users

324

325

326

327

328

329

The previous section described the fitness function applied when individual's fitness was evaluated for managers; here we explain a separate fitness function that is applied when individuals are instead evaluated for users. Individual fitness as calculated for users (F_i^u) is affected by a user's utility for resources (U_{res}^u) and landscape output (U_{land}^u) , and the predicted change in each caused by the user's actions $(\Delta A_i \text{ and } \Delta L_i \text{ for predicted change in resource abundance and summed values of the landscape cells owned by <math>i$, respectively). Individual fitness is defined for users below,

$$F_i^u = \Delta A_i U_{res}^u + \Delta L_i U_{land}^u.$$

Note that F_i^u increases when ΔA_i and ΔL_i are of the same sign as U_{res}^u and U_{land}^u , respectively. Further, in GMSE v0.6, only one term of the equation is nonzero. When land_ownership = FALSE (default, modelling users that harvest resources), $U_{res}^u = -1$ and $U_{land}^u = 0$, and when land_ownership = TRUE, $U_{res}^u = 0$ and $U_{land}^u = 100$ (modelling farmers trying to increase crop yield). Hence users only have a single objective of either decreasing resource abundance or increasing landscape output, though landscape output might be increased indirectly by decreasing resource abundance if res_consume > 0.

381

382

383

Unlike the manager fitness function, the predicted effects of user actions can be defined directly in gmse and gmse_apply. Hence, it is possible to specify how effective a user believes, e.g., culling or scaring to be with respect to their own utility. Arguments to do this include perceive_scare, perceive_cull, perceive_cast, perceive_feed, perceive_help, perceive_tend and perceive_kill. Each of these arguments define how much a user believes one action will affect either the user or the landscape. For example, if perceive_scare = -1, then a user will perceiving scaring as decreasing the number of resources feeding on their landscape by 1. A value of perceive_feed = 0.5 would correspond to a user perceiving feeding to increase the number of resources by one half. Landscape effects (perceive_tend and perceive_kill) refer to effects of actions on the landscape, such that perceive_tend = 0.2 would mean that a single action of tending crops (i.e., action taken on a single landscape cell) is perceived to increase crop yield by 0.2, while perceive_kill = -1 would mean that a single action of killing crops will remove all yield on the landscape cell.

By default, arguments affecting how users perceive the efficiacy of their own actions are set to NA. Default values are then calculated from other arguments specified in gmse or gmse_apply. Default user actions are predicted to affect resources in the following way (in the below E[offspring] is calculated in the same way as in the manager's fitness function):

- scaring decreases resource number by 1 times one minus the number of landscape cells that the user owns (i.e., perceive_scare = -1 * (1 pr_cells_owned)). This accounts for the increasing probability that resource will be scared back to another landscape cell owned by the focal user. If a user owns no cells, then scaring is assumed to have no effect.
- culling decreases resource number by 1 + E[offspring] (i.e., perceive_cull = -1 * (1 + E_off)).
- castration decreases resource number by E[offspring] (i.e., perceive_cast = -1 * E_off).
- feeding increases resource number by E[offspring] (i.e., perceive_feed = E_off).
- help_offspring increases resource number by 1 (i.e., perceive_help = 1).

The number of each action performed is multiplied by its effect, and the sum of all these products is the predicted ΔA_i ,

$$\Delta A_i = (\lambda) Feeds + Helps - Scares - Culls - (\lambda) Castrations.$$

There are only two possible actions that users can take to directly affect landscape output, tending crops (tend_crops) and killing crops (kill_crops). The increase in landscape output is modulated by the parameter tend_crop_yld (ϕ). User actions are therefore predicted to have the following effects for one landscape cell:

- tend_crops will increase landscape output by ϕ (i.e., perceive_tend = tend_crop_yld).
- kill_crops will decrease landscape output by 1 (since the output of a cell is 1 by default, this action removes all output on a landscape cell; i.e., perceive_kill = -1).

Actions on resources can also have indirect effects on ΔL_i when resources consume output on the landscape; we define the value res_consume as r. The predicted ΔL_i is then,

$$\Delta L_i = (\phi) Tends - Kills - r \Delta A_i$$
.

That is, the change in landscape output equals the increase in output from tending crops, minus the number of crops destroyed, minus the change in resource abundance times the effect that resource abundance has on landscape output (note that if user actions decrease resource abundance, then this last term will be positive, increasing landscape output).

³⁹⁰ Choosing genetic algorithm parameter values

Options for adjusting genetic algorithm parameter values in gmse and gmse_apply are shown below.

GMSE argument	Default	Description
ga_popsize	100	The number of individuals in the population temporarily simulated during a single run of the genetic algorithm.
ga_mingen	40	The minimum number of iterations that a genetic algorithm will run before settling on an agent's strategy.
ga_seedrep	20	The number of individuas in the population to be initiaised with the current agent's strategy (e.g., from a previous time step in the broader GMSE simulation), as opposed to being initialised with random strategies.
ga_sampleK	20	For the tournament step of the genetic agorithm, how many strategies are selected at random from the larger population (with replacement) to be included a the tournament.
ga_chooseK	2	Four the tournament step of the genetic agorithm, how many strategies are selected as winners of the tournament, to be included in the next iteration.
ga_mutation	0.1	The mutation rate of any action in an agent's strategy
ga_crossover	0.1	The crossover rate of any action in an agent's strategy; crossover events occur with a different randomly selected strategy in the population.
ga_converge_crit	0.1	The percent increase in strategy fitness from one iteration to the next below which the convergence criteria is satisfied. Iterations wil continue as long as fitness increase is above this convergence criteria.
group_think	FALSE	Whether or not all users (i.e., not including the manager) have identical strategies. If TRUE, then one genetic algorithm will be run and applied to all users.

Given the heuristic goals of the genetic algorithm to mimic the goal-oriented behaviour of agents, default parameters are typically sufficient for agent decision making. Key parameters can be adjusted if more precision in decision making is desired, but these adjustments will come at a cost of simulation efficiency. For example, increasing ga_popsize or ga_mingen, or decreasing ga_converge_crit, might fine tune strategies more effectively, but this will cause the genetic algorithm to take longer every time that it is run, ultimately slowing down GMSE simulations. Alternativey, setting group_think = TRUE will greatly speed up GMSE simulations when many users are being simulated, but this comes at the cost of among-user variation in decision making. Overall, we recommend first using default values in the genetic algorithm before exploring how other parameter value options affect simulation dynamics; for a more general discussion about selecting parameter values in genetic algorithms, see Hamblin (2013).

402 Future development of fitness functions

The fitness functions defined above are useful heuristics for simulating manager and user decision-making in a way that produces realistic, *I know it when I see it*, strategies. Future versions of GMSE might improve upon these heuristics to generate more accurate or more realistic models of human decision making. Such improvements could incorporate additional information such as memory of actions from multiple past time steps, or a continually updated estimate for how actions are predicted to affect resource abundance or landscape output in a simulation (e.g., through a dynamic manager_sense). Alternatively, future improvements could usefully incorporate knowledge of human decision making collected from empirical observation of human behaviour during conservation conflicts. While such possibilities could be useful for future GMSE modelling,

- 411 repeated simulations demonstrate the ability of the current GMSE genetic algorithm to find adaptive strategies
- 412 for managers attempting to keep resources at target abundance, and users attempting to maximise their
- 413 harvests or crop yields. It is therefore useful as a tool for modelling manager and user decisions in a generalised
- 414 management strategy evaluation framework.
